Abstract

We study the theoretical and phenomenological consequences of modifying the Kähler potential of the MSSM two Higgs doublet sector. Such modifications naturally arise when the Higgs sector mixes with a quasi-hidden conformal sector, as in some F-theory GUT models. In the Delta-deformed Supersymmetric Standard Model (DSSM), the Higgs fields are operators with non-trivial scaling dimension $1 < \Delta < 2$. The Kähler metric is singular at the origin of field space due to the presence of quasi-hidden sector states which get their mass from the Higgs vevs. The presence of these extra states leads to the fact that even as $\Delta \rightarrow 1$, the DSSM does not reduce to the MSSM. In particular, the Higgs can naturally be heavier than the W - and Z -bosons. Perturbative gauge coupling unification, a large top quark Yukawa, and consistency with precision electroweak can all be maintained for Δ close to unity. Moreover, such values of Δ can naturally be obtained in string-motivated constructions. The quasi-hidden sector generically contains states charged under $SU(5)_{GUT}$ as well as gauge singlets, leading to a rich, albeit model-dependent, collider phenomenology.

1 Introduction

The origin of electroweak symmetry breaking remains poorly understood. Though low energy supersymmetry provides a promising framework for addressing the hierarchy problem, the absence of any evidence from LEP, the Tevatron, and the LHC already places strong constraints on many supersymmetric models. For example, pushing the superpartner masses up in the Minimal Supersymmetric Standard Model (MSSM) leads to a level of fine tuning which is on the order of (at least) $1\% - 0.1\%$ in many models.

From a top-down perspective, however, the MSSM can be viewed as one very particular supersymmetric field theory. Various SUSY-preserving or SUSY-breaking deformations of this theoretical structure are in principle possible. For example, two basic inputs in a supersymmetric field theory are the Kähler potential and the superpotential, both of which can be supplemented in phenomenological models by SUSY-breaking terms. While holomorphy considerations constrain the superpotential, the Kähler potential is far less constrained. In this regard, the assumption of a canonical Kähler potential in the MSSM is a rather special choice. Although it is the unique renormalizable choice, in the spirit of effective field theory, more general choices are *a priori* equally plausible.

In this paper, we study the consequences of giving the Higgs sector a Kähler metric which is singular at the origin of field space. This can occur when the Higgs fields couple to a quasi-hidden sector in which at least some of the states of the hidden sector get their mass from the Higgs vevs. From a top-down perspective, this sort of visible sector/hidden sector mixing is quite well-motivated. For example, in GUT models arising within F-theory, the Standard Model is realized on a stack of branes, and natural hidden sectors arise when additional branes are in the vicinity of the Standard Model stack. This leads to additional states charged under $G_{SM} = SU(3) \times SU(2) \times U(1)$ which mix with the Standard Model. The hidden sector has $SU(5)_{GUT}$ as a weakly gauged flavor symmetry. In many well-motivated examples, the states fill out vector-like pairs of representations of $SU(5)_{GUT}$. However, they are assumed to get their mass predominantly from Higgs vevs. Within string theory, this can happen naturally.¹ Both of these features will turn out to be relevant for phenomenology.

In contrast to much of the model-building literature, these systems provide concrete $\mathcal{N} = 1$ superconformal field theories which are *different* from (conformal) SQCD. In these D3-brane CFTs, the hidden sector does not induce a Landau pole, and can actually improve

¹The reason these states remain light in the string theory context is that the bare mass of these vector-like states is controlled by the position of the D3-brane relative to the Standard Model branes. Fluxes which attract the D3-brane to the SM branes thus lead to massless states. See [1–5] for recent work on these quasi-hidden sectors. Let us note that in previous studies of these quasi-hidden sectors, the case of a D3-brane slightly displaced (at energy scales far below the GUT scale) from the Standard Model stack was mainly treated. In this paper we instead focus on the limit where this displacement vanishes and the Higgs vevs are the main source of CFT breaking effects.

precision unification [5]. Further, the contribution to the anomalous dimensions of Standard Model fields is small, allowing these states to retain their weakly coupled identity [5]. Finally, since these CFTs involve one, or at most two D3-branes, they do not have a conventional AdS dual, which would have involved a large number of D3-branes.

We can state the main features of the system we shall be studying in purely field theoretic terms, as we will not need many explicit features of the string constructions. The reader interested in string theory details is encouraged to refer to Appendix A and references therein. In the UV, the Higgs sector mixes with the hidden sector via:

$$\delta L_{mix} = \int d^2\theta (H_u \mathcal{O}_u + H_d \mathcal{O}_d) + h.c. \quad (1.1)$$

where the $\mathcal{O}$'s are operators in some hidden sector. Scenarios of electroweak symmetry breaking involving such mixing terms have been considered previously in [6–9]. When there is non-trivial mixing between the two sectors, we expect that at lower scales there is an approximately conformal phase where H_u and H_d pick up non-trivial scaling dimensions Δ_u and Δ_d . We refer to this deformation of the MSSM as the Delta-deformed Supersymmetric Standard Model (DSSM). Our main interest will be in the regime where the excess Higgs dimension $\Delta - 1$ is small.

We assume that at a scale Λ_{soft} , the Higgs sector is deformed by the analogue of the soft breaking parameters in the usual MSSM:²

$$\delta L_{Higgs} = \left(\int d^2\theta \mu H_u H_d + h.c. \right) + (B H_u H_d + h.c.) + m_u^2 \|H_u\|^2 + m_d^2 \|H_d\|^2. \quad (1.2)$$

The full details of the Higgs potential are then fixed by the Kähler potential K . We do not know the precise form of K , but using simple scaling arguments, it is possible to deduce some generic features of the DSSM Higgs potential. In the DSSM Higgs potential, the presence of fractional powers of fields in the Kähler metric leads to a competition between at least two terms in the Higgs potential of degree close to two, such as $|H|^{2+2\delta}$ and $|H|^{2-2\delta}$ where $\delta = \Delta - 1$ is the excess Higgs dimensions. This leads to a squeezed Mexican hat potential, in which the vev is naturally much smaller than the Higgs mass. We find using general arguments that the lightest Higgs mass M_H is related to the gauge boson mass M_V by:

$$\frac{M_H}{M_V} \sim \frac{\sqrt{\delta}}{g} \times (\sqrt{q_0})^{1/\delta}, \quad (1.3)$$

where g is a gauge coupling, and $q_0 < 1$ is an order one parameter fixed by the details of

²Throughout this work, we shall make the assumption that the dimensions of operators are additive, even for non-chiral combinations. This is not true for non-chiral operators, but we expect this is a subleading effect, at least in the limit where $\Delta \rightarrow 1$. Away from this limit, it is a simplifying assumption we make. See [10–12] for recent discussion on this issue.

the Higgs potential. We also check the form of these expressions for a particular choice of Kähler potential.

As $\Delta \rightarrow 1$, the Higgs becomes parametrically heavier than the gauge bosons. This illustrates an important feature of the DSSM: No matter how close Δ gets to one, there is an additional minimum in the Higgs potential which is not present in the case when $\Delta = 1$. It is this feature which eliminates the usual fine tuning present in the Higgs sector of the MSSM. In the regime $\Delta \rightarrow 1$, the extra states of the DSSM can be viewed very roughly as additional vector-like generations, but where an effectively non-integer number of fields contribute to the gauge coupling beta functions. As $\Delta \rightarrow 2$, one is far from the regime of weak coupling. In this limit, the Kähler potential may include terms such as $\sqrt{H^\dagger H}$, which is more in line with a composite Higgs. See for example [6–9, 13–17] for other recent work on coupling the Higgs to a strongly coupled hidden sector.

The regime of small $\delta = \Delta - 1$ is attractive for a number of reasons. In this case, the top quark Yukawa can remain reasonably large, as it is close to being a marginal coupling. Further, when $\delta \leq 0.1$, perturbative gauge coupling unification is retained [5] (see also [18]). As we explain later, the regime $0.01 \leq \delta \leq 0.1$ is also favored by constraints from precision electroweak physics. Such values of δ can also be naturally obtained in explicit models [5].

In summary, the characteristic mass scales of the DSSM are:

$$M_V \sim \Lambda_{soft} \times g \times (\sqrt{q_0})^{1/\delta} \quad (1.4)$$

$$M_H \sim \Lambda_{soft} \times \sqrt{\delta} \quad (1.5)$$

$$M_{extra} \sim 4\pi v \times \sqrt{\delta} \sim (3 \text{ TeV}) \times \sqrt{\delta} \quad (1.6)$$

where M_{extra} is the mass of the extra states which get their mass from the Higgs vev, and lead to the singular behavior in the Kähler potential.

The presence of these extra states is motivated by UV considerations, but has direct consequences for experiment. Indeed, since these extra states couple to the Higgs, they will be charged under G_{SM} . Another common feature of these quasi-hidden sectors is the presence of additional SM gauge singlets which participate in the strongly coupled hidden sector. The signatures of this framework have considerable overlap with a particular class of hidden-valley models [19, 20]. See also [21–24] for related work on the phenomenology of unparticle scenarios with a mass gap, and in particular [6, 15] for some discussion of the consequences for Higgs physics.

The rest of this paper is organized as follows. First, in section 2 we describe the general setup. In section 3 we study the mass scales of the DSSM. In section 4 we discuss precision electroweak constraints, and in section 5 we discuss some qualitative features of the associated collider phenomenology. Section 6 contains our conclusions. In the Appendices we present some additional details and explicit examples.

2 General Setup

In this section we state the general setup for the DSSM. We assume that in the ultraviolet regime, e.g. the GUT/string scale, the field content of the Standard Model is weakly coupled to a strongly coupled quasi-hidden sector. From the perspective of the hidden sector, the Standard Model gauge group is simply a weakly gauged flavor symmetry, according to which the operators must be organized. Thus, these operators will in general transform under some representation of the Standard Model gauge group.

At this high energy scale, we add interaction terms between the two sectors. For our purposes, these can be summarized as mixing $\mathcal{O}_{MSSM}\mathcal{O}_{HID}$ between operators $\mathcal{O}_{MSSM}$ of the MSSM and $\mathcal{O}_{HID}$ of the hidden sector. It is worth noting that in many cases of interest, the hidden sector may not even possess a Lagrangian formulation. In such cases, the meaning of this operator deformation is that it is to be inserted into the correlation functions for the theory. We focus on mixing between the Higgs and hidden sectors via the F-terms:

$$\delta L_{mix} = \int d^2\theta (H_u \mathcal{O}_u + H_d \mathcal{O}_d) + h.c.. \quad (2.1)$$

Such couplings naturally arise in string inspired models where operators from a D3-brane sector such as $\mathcal{O}_u$ and $\mathcal{O}_d$ couple to Standard Model operators localized on a seven-branes. Our main assumption (which can be justified in some string models) is that these deformations are relevant in the UV theory and cause the Higgs fields to develop a non-trivial (but not very different from one) scaling dimension in the IR. See [6–9] for recent work on related scenarios of electroweak symmetry breaking involving the effects of such couplings.

In general we can say relatively little when the mixing between the Higgs fields and $\mathcal{O}$ operators is large. However, in the limit where the Higgs dimensions stay close to one, we can exercise more control. This type of behavior can be realized, as in the examples of [5]. Such deformations often trigger a renormalization group flow to a new interacting conformal fixed point. One way of characterizing this behavior is that in flowing from the UV to the IR, the fields H_u and H_d pick up non-trivial scaling dimensions. Denote by Δ_u and Δ_d the scaling dimensions of the Higgs fields H_u and H_d . It is also helpful to introduce:

$$\Delta \equiv \frac{\Delta_u + \Delta_d}{2}, \quad \delta \equiv \Delta - 1. \quad (2.2)$$

We shall often use Δ to characterize the effects of non-trivial Higgs scaling dimensions. As will become clear, the regime $\Delta \approx 1$ appears to be most natural. Thus we often limit our analysis to an expansion in small δ .

Of course, in the real world, we never reach such a fixed point. This is because supersymmetry is broken at some scale, so conformal symmetry must be broken at this scale or above. We assume that the energy scale where this breakdown of conformal symmetry

occurs depends on the soft mass scale Λ_{soft} . This scale enters through the μ -term, $B\mu$ -term, and the analogue of the soft mass terms, which we assume are all given by powers of Λ_{soft} , up to order one coefficients³. We now discuss each of these terms.

The μ -term is an F-term and is holomorphic in the chiral operators H_u and H_d . The superpotential is $\mu H_u H_d$, so μ scales as $\mu = \mu_0 \Lambda_{soft}^{3-\Delta_u-\Delta_d}$, with μ_0 a dimensionless constant. Similarly, because the $B\mu$ term involves the descendant of a chiral operator, we have a term $BH_u H_d + h.c.$ in the Lagrangian density. Because this term involves the scalar components of chiral operators, the coefficient B is fixed as $B = B_0 \Lambda_{soft}^{4-\Delta_u-\Delta_d}$, with B_0 a dimensionless constant.

The analogue of soft mass terms in the DSSM is more subtle. In the absence of supersymmetry, it is difficult to constrain the form of such contributions. However, with supersymmetry, we expect these contributions to be generated by two-point functions involving the Higgs fields⁴. We shall therefore make the natural assumption that these soft masses are of the form:

$$m_u^2 \|H_u\|^2 + m_d^2 \|H_d\|^2, \quad (2.3)$$

where the norm appearing in $\|H\|^2$ is with respect to the Kähler metric, so that $\|\Phi\|^2 = \Phi^i g_{i\bar{j}} \Phi^{\bar{j}\dagger}$. Scaling arguments then imply $m = m_0 \times \Lambda_{soft}$ for m_0 a dimensionless number. Note that the naive engineering dimensions for soft masses work out since the Kähler potential has dimension two.

In more formal terms, the full deformation is:⁵

$$\mathcal{O}_{deform} = \left(\int d^2\theta \mu H_u H_d + h.c. \right) + (BH_u H_d + h.c.) + m_u^2 \|H_u\|^2 + m_d^2 \|H_d\|^2. \quad (2.4)$$

The requirement that supersymmetry is softly broken is that the parameters B , m_u^2 , and m_d^2 tend to zero as $\Lambda_{soft} \rightarrow 0$. For the soft masses, this does not impose a condition on the dimensions. Note, however, that vanishing of the $B\mu$ term then requires $\Delta < 2$. Although the μ -term is compatible with supersymmetry, if we also assume that this vanishes as

³In this work, we do not discuss the dynamical mechanism by which supersymmetry is broken. Instead, we assume supersymmetry breaking and discuss the nature of the soft terms consistent with the structure of the framework. As a simplifying assumption, in this work we assume that supersymmetry breaking is decoupled from the dynamics of the quasi-conformal hidden sector. It would be interesting to relax this assumption.

⁴For example, this happens in minimal gauge mediation.

⁵The more precise characterization of this deformation is as follows. We suppose that the Higgs fields interact with a strongly coupled field theory which flows in the infrared to a strongly coupled conformal theory. As we flow to the infrared, we suppose that at a scale Λ_{soft} this theory is deformed by an operator $\mathcal{O}_{deform}$. This means all correlators are to be evaluated with insertions of $\exp \int d^4x \mathcal{O}_{deform}$. Even the precise definition of this deformation contains subtleties, because the various terms involve bilinears in operators of the strongly coupled theory. What is meant here is that all operators are to be evaluated with respect to the operator product expansion, with the constant part removed.

$\Lambda_{soft} \rightarrow 0$, we obtain the sharper bound $\Delta < 3/2$. We shall consider the weaker bound to keep our discussion more general. Finally, we note that we can in principle also include four-point functions involving the Higgs fields. However, we will find that the terms which are close to degree two dominate over such contributions, so in what follows we neglect such terms.

Given these operator deformations, we are interested in analyzing the resulting low energy behavior of the system. By using general scaling arguments, we will show that after adding these operator deformations, the Higgs develops a vev at some lower scale. We would then like to determine some features of the low energy spectrum of states. Since there is a characteristic mass scale for the theory, it makes sense to speak of an effective potential for the Higgs fields, and in particular, to track the energy of the vacuum as a function of the Higgs vevs.

2.1 The Kähler Potential

The precise form of the Kähler potential clearly plays a crucial role in determining the precise mass spectrum of the Higgses. In $\mathcal{N} = 1$ supersymmetric theories in general, the Kähler potential is renormalized and it is not possible to determine its precise form, especially in a strongly coupled setting. Hence, we will consider particular examples of Kähler potentials consistent with our general setup. Although the detailed results for the mass spectra and the resulting phenomenology will vary with the choice of the Kähler potential, we expect these examples to be representative of a large class of Kähler potentials, at least as far as qualitative features are concerned.

In order to motivate the choice of Kähler potential which we use later, consider the special case where the dimension of the Higgs field is one. Then we can use the one-loop Coleman-Weinberg correction to the canonical Kähler potential [25, 26]:

$$K = K_{(0)} + K_{1-loop} = H^\dagger H - \frac{1}{32\pi^2} \text{Tr} \left(\|M\|^2 \log \frac{\|M\|^2}{\Lambda_{UV}^2} \right) \quad (2.5)$$

to capture the effects of couplings to a hidden sector which gets its mass from Higgs vevs. Here, the trace runs over the supermultiplets of the theory, $\|M\|^2$ are the masses squared of the various states, and Λ_{UV} is a UV cutoff. In the weakly coupled limit, $\|M\|^2 = 32\pi^2 \times \hat{\delta} \times H^\dagger H$ for some constant $\hat{\delta}$. We can then write:

$$K_{\log} = H^\dagger H \left(1 - \hat{\delta} \log \frac{H^\dagger H}{\Lambda_{(0)}^2} \right) \quad (2.6)$$

where $\Lambda_{(0)}$ is some high-scale where new physics come in. The $K_{\log}$ Kähler potential can

be viewed as a limiting case of a Kähler potential:

$$K_{\Delta} \equiv (H^{\dagger} H)^{1/\Delta} \quad (2.7)$$

where H has dimension $\Delta = 1 + \delta$, with the identification $\delta \sim \widehat{\delta}$. Note that K_{Δ} provides a “completion” of the metric in the sense that all higher powers in $K_{\log}$ are resummed. Hence, important features of having a non-trivial scaling dimension may be missed in the leading log approximation. This will become clear in section 3.1.1.

In writing the Kähler potential as K_{Δ} we have assumed that the dimension of $H^{\dagger} H$ equals 2Δ . This is not true in general, but provided it is close to 2Δ , which is a conservative assumption when Δ is near one, our main conclusions will not change. For simplicity of presentation, however, in what follows we shall take $H^{\dagger} H$ to have dimension exactly 2Δ . In the small δ limit, $x^{1/\Delta} = x(1 - \delta \log x)$, which reproduces the behavior of the weakly coupled example. Of course, in reality, the form of the Kähler potential could be more complicated. The main qualitative condition we shall be concerned with here is situations where the Kähler potential is singular in the $H \rightarrow 0$ limit and (2.7) is a simple example satisfying this criterion. The absence of a mass scale in equation (2.7) also indicates that this is perhaps indicative of a conformal sector. In realistic conformal theories, one does not expect the Kähler potential to take exactly the form of K_{Δ} . However, it is worth noting that in some situations with $\mathcal{N} = 2$ supersymmetry, this expression is exact (see for example [27] and [28]).

Self-consistency of our approximation dictates that the Higgs vev is the dominant source of mass for at least some of the states of the hidden sector. We note that even if the mass spectrum in the quasi-hidden sector is not exactly supersymmetric, this behavior will continue to hold. For example, while the MSSM scalars can have mass contributions not proportional to the Higgs vevs, the fermion masses are proportional to the Higgs vev. In the small δ limit, we can estimate these masses as follows. Comparing the form of the Coleman-Weinberg potential to the form of the Kähler potential $K_{\log}$, we identify:⁶

$$M_{extra} \simeq 4\pi v \times \sqrt{\delta} \quad (2.8)$$

where $v \simeq 246$ GeV is the Higgs vev.

What is the regime of validity of our setup? We expect that our discussion is valid up to energy scales where one loop corrections can destabilize the form of the effective potential. Indeed, since the potential arising from the deformation (2.4) contains fractional powers of the fields, expanding around a fixed vev will lead to a field theory with an arbitrary number of higher point interactions. The higher-point interactions can renormalize the

⁶Here we have made an implicit assumption that the coupling associated to $H\mathcal{O}$ is an order one number, with some natural notion of canonical normalization for the Higgs fields.

lower-point interactions by closing some of the external legs. In order for these loop effects to not overwhelm the tree-level effects, the loop momenta must be bounded from above. Hence, roughly viewing the mass scale for the Higgs vev v as a decay constant, we expect the effective potential to be valid up to a scale:

$$\Lambda_{(0)} \simeq 4\pi v \simeq 3 \text{ TeV}. \quad (2.9)$$

Let us note that this is a conservative assumption, the range of validity may be higher due to cancellations from superpartners.

2.2 The Extra States

As we have seen, in the DSSM, there are extra states which get their mass from the couplings:

$$\int d^2\theta \ (H_u \mathcal{O}_u + H_d \mathcal{O}_d). \quad (2.10)$$

Let us discuss some further properties of these extra states. We assume that some of the hidden sector states get most of their mass from the Higgs vevs. One could imagine that supersymmetry breaking causes some of the bosons to be heavier than their fermionic superpartners, just as in the MSSM. This will not change the fact that some states get their mass mainly from the Higgs vevs.

Depending on the precise size of these mixing terms, the mass of these extra fermionic states can be either above or below the TeV scale. In principle, one can introduce additional mass terms for these vector-like states in order to remove them from the low-energy spectrum. This is possible but runs counter to our goal of having light states charged under $SU(2) \times U(1)$ with mass induced primarily by the Higgs vev⁷.

Of course, we do not know the precise form of the hidden sector states. However, in the weakly coupled limit where a Coleman-Weinberg like analysis is valid, there is a qualitative similarity to a vector-like fourth generation with field content $Q^{(4)} \oplus \tilde{Q}^{(4)}$, $U^{(4)} \oplus \tilde{U}^{(4)}$, $D^{(4)} \oplus \tilde{D}^{(4)}$, $L^{(4)} \oplus \tilde{L}^{(4)}$, $E^{(4)} \oplus \tilde{E}^{(4)}$, where the superscript (4) indicates only that these are all fourth-generation states. Here, the operators $\mathcal{O}_u$ and $\mathcal{O}_d$ are:

$$\mathcal{O}_u = \kappa_{QU} Q^{(4)} U^{(4)} + \tilde{\kappa}_{QD} \tilde{Q}^{(4)} \tilde{D}^{(4)} + \tilde{\kappa}_{LE} \tilde{L}^{(4)} \tilde{E}^{(4)} + \kappa_{LS} L^{(4)} S_u + \dots \quad (2.11)$$

$$\mathcal{O}_d = \tilde{\kappa}_{QU} \tilde{Q}^{(4)} \tilde{U}^{(4)} + \kappa_{QD} Q^{(4)} D^{(4)} + \kappa_{LE} L^{(4)} E^{(4)} + \tilde{\kappa}_{LS} \tilde{L}^{(4)} S_d + \dots \quad (2.12)$$

We have included an additional vector-like pair of hidden sector singlets $S_u \oplus S_d$. The values of the κ 's affect the masses of these additional states. We see that all these fields can be expected to participate in multiple interactions.

⁷As explained in the Introduction, this can naturally happen in some string constructions.

It is important to note that the description of the $\mathcal{O}$'s above as a vector-like fourth generation is at best very rough and *qualitative*. The “...” reflects our lack of knowledge of the structure of $\mathcal{O}_u$ and $\mathcal{O}_d$. For example, the beta function contributions to the SM gauge couplings coming from the hidden sector are in general non-integral (as in [5]), hence the hidden sector states should not literally be viewed as a vector-like fourth generation.

The presence of additional states charged under the SM gauge group will in turn affect the running of the gauge couplings. One concern is that if these extra states do not fill out GUT multiplets, gauge coupling unification will be distorted. Another concern is that even if these states do fill out complete GUT multiplets, the presence of many additional states can produce Landau poles at low energies.

The first concern is naturally solved in models where $SU(5)_{GUT}$ is a flavor symmetry. The second concern can also be bypassed by taking δ sufficiently small, since δ is what enters into the numerator of the NSVZ beta function. As found in [5], there exist explicit string theory scenarios where gauge coupling unification can be retained, even when the threshold is on the order of the weak scale (see also [18]).⁸

Finally, the hidden sector may also include additional states which are not charged under the SM gauge group. This is the situation, for example, in the probe D3-brane theories considered in [5]. Because not all such states couple to the SM, one expects that some of these states will be lighter than their counterparts charged under G_{SM} . We shall return to the phenomenological consequences of these additional states in section 5.

2.3 The Range of δ

In this section we discuss bounds on the Higgs dimensions. We phrase our discussion in terms of Δ_u, Δ_d and the excess dimension $\delta = (\Delta_u + \Delta_d)/2 - 1$. There is a general lower bound coming from the fact that the extra charged states cannot be too light. Taking for concreteness $M_{top} \simeq 175 \text{ GeV} \lesssim M_{extra} \simeq \Lambda_{(0)} \times \sqrt{\delta} \simeq (3 \text{ TeV}) \times \sqrt{\delta}$, it is clear that δ is at least of order 3×10^{-3} . Assuming the couplings $H_u Q U$ and $H_d Q D$ are generated at the GUT scale, making the Higgs a higher dimension operator means that the top and bottom Yukawas will experience some conformal suppression:

$$\lambda_{top}(M_{top}) \sim 3 \times \left(\frac{M_H}{M_{GUT}} \right)^{\Delta_u + \Delta_Q + \Delta_U - 3}, \quad \lambda_{bot}(M_{bot}) \sim 3 \times \left(\frac{M_H}{M_{GUT}} \right)^{\Delta_d + \Delta_Q + \Delta_D - 3}. \quad (2.13)$$

⁸Let us note that in the models in [5], additional couplings between the Standard Model and quasi-hidden sector were also included, which in turn further shift the scaling dimensions of the MSSM fields. A small variant on the models of [5] can be arranged by switching off these additional F-term mixing terms. Alternatively, these additional couplings can be retained and their effect examined. In this work, we omit these terms for simplicity. The main point here is that the requirements for gauge coupling unification can be met in explicit models.

The factor of three comes from running from the GUT scale down to the weak scale. This assumes that flavor is generated at the GUT scale, as is natural in F-theory GUT models. For example, taking $M_H/M_{GUT} \sim 10^{-13}$, we see that $3 \times (M_H/M_{GUT})^{0.01} \sim 2$, while $3 \times (M_H/M_{GUT})^{0.1} \sim 0.2$. Thus, $0.01 \lesssim \delta \lesssim 0.1$ is naturally consistent with a large top Yukawa. A relevant issue in this regard is whether other SM fields are assumed to mix slightly with the D3-brane states. This is true in the examples considered in [5], although not strictly necessary for a field theory realization of the small δ regime. In this work, for simplicity and concreteness, we consider UV deformations where only the Higgs fields mix with the hidden sector, since otherwise one has to also include non-oblique corrections to electroweak precision observables. However, it is worth noting that such mixings can be potentially beneficial. For example, when the $\bar{5}_M$ also has a non-trivial scaling dimension, this can lead to conformal suppression of the bottom Yukawa relative to the top Yukawa, so that a low $\tan \beta$ can be easily arranged.

In summary, we see that the viable range of values for δ is:

$$0.01 \lesssim \delta \lesssim 0.1. \quad (2.14)$$

As we explain later, in the above region of δ , the DSSM can be consistent with precision electroweak constraints without much tuning. Quite fortuitously, this is also the range which naturally occurs in the models of [5]!

3 Mass Scales in the DSSM

In this section we estimate the Higgs and gauge boson masses in the DSSM. Based on the general considerations of section 2, we focus primarily on the small δ regime. Since we do not know the precise form of the Kähler potential in general, it is more reliable to provide general scaling estimates. In subsection 3.1 we show that the Higgs vev can naturally be far lower than the lightest Higgs mass. We then study the gauge boson masses in the presence of a non-trivial Kähler potential. See Appendix B for some explicit examples.

3.1 Symmetry Breaking in a Squeezed Mexican Hat

We now study symmetry breaking for the DSSM Higgs potential. The basic idea is that there are four relevant operators in this potential: two soft mass terms, the $B\mu$ -term, and the supersymmetry-preserving μ -term. Although there is also a D-term potential, it is subdominant because it comes from an irrelevant operator. In the MSSM, the very irrelevance of the D-term is responsible for the Little Hierarchy problem. By contrast, in the DSSM, the Higgs mass can be far higher than the mass scale set by its vev.

Before discussing a particular example, let us first explain in general terms why the form of the effective potential changes so drastically compared to the standard MSSM Higgs potential. The cause of this change can be traced to a competition between terms of degree close to two. At small field range, these terms dominate over the irrelevant D-term contribution. For a field H of small excess dimension $\delta = \Delta - 1$, the role of the quartic in the standard Mexican hat potential is, at very small field range, instead taken up by the μ -term:

$$V_{eff} \supset |\mu|^2 |H|^{2+2\delta}. \quad (3.1)$$

The role of the tachyonic mass term in the usual Mexican hat potential can in principle be played by lower degree terms such as $|H|^{2-2\delta}$ or $|H|^2$, which respectively originate from the soft masses or the $B\mu$ -term. Only one such term is really necessary to produce a stabilized potential, but in a generic situation we can expect both to be present. These tachyonic contributions are at least as relevant as a usual mass term in a Mexican hat potential. Balancing the μ -term against one of these contributions, the net effect is a squeezed Mexican hat potential. See figure 1 for the general behavior of such functions as δ is varied.

Having illustrated the general idea, let us now consider a toy model which exhibits this behavior. Consider a single chiral superfield X of dimension Δ_X and Kähler potential $K = (X^\dagger X)^{1/\Delta_X}$. In what follows we assume that the dimension of $X^\dagger X$ is $2\Delta_X$, which is a good approximation in many examples but which may be relaxed, see [10–12]. In this setting, we now show that the analogue of the soft supersymmetry breaking terms in the Higgs sector lead to a mass for X which is far above the vev $|\langle X \rangle|^{1/\Delta_X}$. With this choice of Kähler potential, the Kähler metric is

$$g_{X\bar{X}} = \frac{1}{\Delta_X^2} \frac{|X|^{2/\Delta_X}}{|X|^2} \quad (3.2)$$

and the effective kinetic term is:

$$L_{kinetic} = -\frac{1}{\Delta_X^2} \frac{|X|^{2/\Delta_X}}{|X|^2} |\partial_\mu X|^2. \quad (3.3)$$

Motivated by the arguments in section 2 we study the following scalar potential:

$$\begin{aligned} V &= m^2 g_{X\bar{X}} |X|^2 - B |X|^2 + |\mu|^2 g^{X\bar{X}} |X|^2 \\ &= \frac{m^2}{\Delta_X^2} |X|^{2/\Delta_X} - B |X|^2 + \Delta_X^2 |\mu|^2 |X|^{(4\Delta_X-2)/\Delta_X} \\ &\simeq A |X|^{2-2\delta_X} - B |X|^2 + C |X|^{2+2\delta_X} \end{aligned} \quad (3.4)$$

where $A \equiv m^2/\Delta_X^2 \simeq m_0^2 \Lambda_{soft}^2 (1-2\delta_X)$, $B \simeq B_0 \Lambda_{soft}^{2-2\delta_X}$, and $C \equiv |\mu|^2 \Delta_X^2 \simeq |\mu_0|^2 \Lambda_{soft}^{2-4\delta_X} (1+$

Figure 1: Cartoon plot of the family of functions $V_\delta(x) = -|x|^2 + 2|x|^{2+2\delta}$ for various choices of δ . At δ exactly zero, the non-zero minimum disappears. For $\delta \neq 0$, this leads to a squeezed minimum close to the origin of field space.

$2\delta_X$). Here we have introduced dimensionless order one constants m_0, B_0 and μ_0 as per our discussion in section 2. In comparison to a standard Mexican hat potential, we observe that the exponents are compressed. This leads to an interesting change in the behavior of the potential. The critical points of this potential satisfy:

$$|X_*^{(1)}|^{2(1-\delta_X)} = 0; |X_*^{(2)}|^{2(1-\delta_X)} = \Lambda_{soft}^2 \times (\tilde{q}_0)^{1/\delta_X}; |X_*^{(3)}|^{2(1-\delta_X)} = \Lambda_{soft}^2 \times (q_0)^{1/\delta_X}. \quad (3.5)$$

where q_0 and $\tilde{q}_0$, to leading order in δ_X , are given by :

$$q_0 \simeq \frac{B_0 + t_0}{2|\mu_0|^2}, \quad \tilde{q}_0 \simeq \frac{B_0 - t_0}{2|\mu_0|^2}; \quad t_0 \equiv \sqrt{B_0^2 - 4m_0^2|\mu_0|^2} \quad (3.6)$$

The critical point at zero is special since the second derivative diverges there, reflecting the singularity of the Kähler metric at the origin of field space. Provided the parameters q_0 and $\tilde{q}_0$ are both positive, the other two critical points give rise to a maximum and minimum at $|X_*^{(2)}|$ and $|X_*^{(3)}|$, respectively. Let us note that a symmetry-breaking vev can be achieved even when $m = 0$, or alternatively, when $B = 0$ and $m^2 < 0$. In these limits, the “dip” at the origin of field space again flattens out.

The crucial point to note is that the vev is exponentially suppressed relative to Λ_{soft} when $q_0 < 1$.⁹ In this case, the mass squared of the canonically normalized field X can be

⁹Note that we want q_0 to not be *much* smaller than one, otherwise there will be a huge hierarchy between the vev and Λ_{soft} . The phenomenologically relevant mass scales are discussed in section 3.3.

computed to leading order in δ_X :

$$M_X^2 \simeq \Lambda_{soft}^2 \times \delta_X \times t_0. \quad (3.7)$$

Note that the mass is only suppressed relative to Λ_{soft} by a factor $\sqrt{\delta_X}$, hence the vev is exponentially suppressed relative to the mass. The proximity of low-degree terms explains why the contribution from an ordinary quartic term is negligible; in the low energy theory it is far less relevant than the lower degree terms. What happens when $q_0 > 1$? In that case, our description has broken down since the purported vev is far above Λ_{soft} .

The above analysis can be straightforwardly generalized to models with two Higgs doublets. Symmetry breaking with the Higgs fields is encapsulated in terms of the vevs $v_u = \langle H_u^{(0)} \rangle$ and $v_d = \langle H_d^{(0)} \rangle$, which are related to the two mass scales v_u^{1/Δ_u} and v_d^{1/Δ_d} . It is helpful to parameterize these scales in terms of the characteristic mass scale v and a dimensionless ratio:

$$\frac{v}{\sqrt{2}} = \sqrt{v_u^{2/\Delta_u} + v_d^{2/\Delta_d}}, \quad \tan \beta = \frac{v_u^{1/\Delta_u}}{v_d^{1/\Delta_d}}. \quad (3.8)$$

The general form of the effective potential as a function of v can then be fixed by scaling arguments to be:

$$V(v, \tan \beta) = m^2 v^2 - B v^{2\Delta} + |\mu|^2 v^{4\Delta-2} \quad (3.9)$$

where the dependence on $\tan \beta$ is absorbed in the coefficients. We are implicitly assuming that $\tan \beta$ is a free parameter, the changes in which can be compensated by changes in the supersymmetry breaking parameters¹⁰. The astute reader may notice that the exponents of v are slightly different from those discussed earlier in the context of the toy model involving X . This is because v has canonical dimensions of mass, whereas X did not. Here, the scaling dimensions are $m^2 \sim \Lambda_{soft}^2$, $B \sim \Lambda_{soft}^{4-\Delta_u-\Delta_d}$, $\mu \sim \Lambda_{soft}^{3-\Delta_u-\Delta_d}$, and $\Delta = (\Delta_u + \Delta_d)/2$. Following the same discussion as before, we see that the characteristic vev and mass squared of the lightest Higgs H is:

$$v^2 \simeq \Lambda_{soft}^2 \times (q_0)^{1/\delta}, \quad M_H^2 \simeq \Lambda_{soft}^2 \times \delta. \quad (3.10)$$

In contrast to the usual MSSM, not all of the soft mass terms or even the quartic D-terms are necessary to generate a symmetry-breaking minimum. The μ -term induces a term of degree $2 + 4\delta$, and plays the role of a large quartic term. The soft masses and $B\mu$ -term serve instead as tachyonic masses. The $B\mu$ -term always induces a saddle point, generating a tendency to roll away from the origin of field space. Hence, one can in principle do without the soft mass terms. Conversely, one can consider scenarios where the $B\mu$ -term is absent, and the soft mass terms are tachyonic. These two possibilities are especially tractable and

¹⁰The same is done in phenomenological studies of the MSSM.

are treated in more detail in Appendix B.

Summarizing, we see that the mass of the lightest Higgs is slightly suppressed relative to Λ_{soft} , while its vev is exponentially suppressed. The vev determines the mass of the gauge bosons, leading to a Higgs mass which can naturally be above the gauge boson masses. Hence, we obtain the general relation:

$$\frac{M_H}{M_V} \simeq \frac{\sqrt{\delta}}{g} \times (\sqrt{q_0})^{-1/\delta}. \quad (3.11)$$

3.1.1 The Weakly Coupled Limit

Before moving on to discussing gauge boson masses, it is worth understanding the weakly coupled limit in which the Higgs fields have dimension exactly one. In this case, it is tempting to use the Coleman-Weinberg Kähler potential K_{log} in (2.6) to determine the effective potential and the corresponding vacuum. This is certainly possible to do; however this leads to the following solution for the vev:

$$\delta \log \left(\frac{v^2}{\Lambda_{(0)}^2} \right) \simeq \left(\frac{B - |\mu|^2 - m^2}{|\mu|^2 - m^2} \right) = \mathcal{O}(1), \quad (3.12)$$

The parameters appearing in (3.12) have the usual dimensions since we are in the weakly coupled limit. Since the RHS is generically $\mathcal{O}(1)$ or greater as it is independent of δ , this implies that higher order corrections to the Kähler potential must be taken into account¹¹. Thus, the full Kähler potential K_Δ , which provides a UV completion of K_{log} , is needed to study the vacuum of the theory.

3.2 Gauge Boson Masses

Let us now discuss some further features of the gauge boson mass spectrum. From the perspective of the hidden sector, the Standard Model appears as a weakly gauged flavor symmetry. Since the Higgs fields are, by definition, charged under $SU(2)_L \times U(1)_Y$, we can write down the leading order coupling between the Higgs modes and gauge bosons, as in a general $\mathcal{N} = 1$ supersymmetric field theory:

$$T_{Higgs} = -g_{i\bar{j}} D_\mu \Phi^i D^\mu \Phi^{\dagger\bar{j}}. \quad (3.13)$$

Here, Φ^i is shorthand for the vector of chiral superfields $\Phi = (H_u^{(+)}, H_u^{(0)}, H_d^{(0)}, H_d^{(-)})$, $g_{i\bar{j}}$ is the Kähler metric. Since the flavor symmetry is assumed to be only weakly gauged, the

¹¹Note that precisely the same argument was given by Coleman and Weinberg for not trusting the symmetry breaking solution in one of the examples in [29].

covariant derivative for this four-component vector is given by the usual covariant derivative for the two Higgs doublets H_u and H_d .

A remarkable “accident” of the Standard Model and MSSM is that the heavy gauge bosons ($W^{(+)}$, $Z^{(0)}$, $W^{(-)}$) form an approximate triplet under a custodial $SU(2)$ symmetry. This is no longer guaranteed when the Kähler potential is of a general form. We refer to the “classical contribution” from expanding the Kähler potential around a fixed vev as $M_{W,cl}$ and $M_{Z,cl}$. It is also convenient to introduce the ratio:

$$\rho_{cl} = \frac{M_{W,cl}^2}{c_W^2 M_{Z,cl}^2} \quad (3.14)$$

where $c_W^2 = \frac{g^2}{g^2 + g'^2}$ and g and g' are the gauge couplings of $SU(2)_L$ and $U(1)_Y$, respectively.¹² Violation of custodial $SU(2)$ is controlled by the order parameters $\delta_u = \Delta_u - 1$ and $\delta_d = \Delta_d - 1$. Let us note that the actual ρ -parameter of the DSSM also includes radiative contributions, which are not included in this “classical expression”. We return to this in section 4.

Consider first the case where the Higgs fields both have dimension Δ and the Kähler potential is $K_\Delta = (H_u^\dagger H_u + H_d^\dagger H_d)^{1/\Delta}$. Taking the Higgs vevs to be v_u and v_d , the resulting mass terms for the gauge bosons are:

$$M_{W,cl}^2 = \frac{g^2}{2\Delta} \times (v_u^2 + v_d^2)^{1/\Delta}, \quad M_{Z,cl}^2 = \frac{M_{W,cl}^2}{c_W^2} \times \frac{\left((v_u^2 + v_d^2)^2 + 4v_u^2 v_d^2 (\Delta - 1)\right)}{\Delta (v_u^2 + v_d^2)^2} \quad (3.15)$$

so that ρ_{cl} is:

$$\rho_{cl} \simeq 1 + \left(1 - \frac{4v_u^2 v_d^2}{(v_u^2 + v_d^2)^2}\right) \delta \quad (3.16)$$

and we have expanded in small δ . In the limit of low $\tan \beta$ and large $\tan \beta$, we have:

$$\tan \beta \rightarrow 1 : \rho_{cl} = 1 + \delta \times \varepsilon^2 \quad (3.17)$$

$$\tan \beta \rightarrow \infty : \rho_{cl} = 1 + \delta. \quad (3.18)$$

The reason for the extra suppression by ε in the first case is that K_Δ preserves an $SU(2)_L \times SU(2)_R$ under which the Higgs fields transform in the $(2, 2)$. When $\tan \beta \rightarrow 1$, a diagonal $SU(2)$ is preserved, so the gauge bosons fill out a triplet of the approximate custodial $SU(2)$.

As another example, consider a perhaps more generic situation where H_u and H_d have

¹²Here we neglect convention-dependent subtleties connected with the renormalization of electroweak observables, and in particular, which quantities we treat as fixed inputs, and which are taken as scale dependent (see e.g. [30] and the review [31] for discussion on this point).

respective dimensions Δ_u and Δ_d , with Kähler potential:

$$K = (H_u^\dagger H_u)^{1/\Delta_u} + (H_d^\dagger H_d)^{1/\Delta_d}. \quad (3.19)$$

Computing the gauge boson masses in this case yields, as a function of the Higgs vevs:

$$M_{W,cl}^2 = \frac{g^2}{2} \times \frac{\Delta_d v_u^{2/\Delta_u} + \Delta_u v_d^{2/\Delta_d}}{\Delta_u \Delta_d}, \quad M_{Z,cl}^2 = \frac{g^2 + g'^2}{2} \times \frac{\Delta_d^2 v_u^{2/\Delta_u} + \Delta_u^2 v_d^{2/\Delta_d}}{\Delta_u^2 \Delta_d^2}. \quad (3.20)$$

The value of ρ_{cl} is now:

$$\rho_{cl} \simeq 1 + \frac{\tan^2 \beta \times \delta_u + \delta_d}{\tan^2 \beta + 1}. \quad (3.21)$$

Observe that for this choice of Kähler potential, the more generic estimate is again $\rho_{cl} \simeq 1 + c \times \delta$, where c is a number slightly less than one, and δ is the characteristic dimension of the two Higgs fields. The two limiting cases are:

$$\tan \beta \rightarrow 1 : \rho_{cl} = 1 + \frac{\delta_u + \delta_d}{2} \quad (3.22)$$

$$\tan \beta \rightarrow \infty : \rho_{cl} = 1 + \delta_u. \quad (3.23)$$

3.3 Summary of Mass Scales

To orient the reader, let us now summarize the various mass scales of the DSSM in the small δ regime. The estimates of these scales will appear in our estimates of the behavior of the physical potential. We first express all quantities in terms of the single scale Λ_{soft} .

Proceeding up in energy scales, we first encounter the gauge boson masses. The mass of the W -boson is:

$$M_W = \frac{g v}{2} \simeq \frac{g}{2} \times \Lambda_{soft} \times (\sqrt{q_0})^{1/\delta} \quad (3.24)$$

where $q_0 < 1$ is an order one number. We see that M_W is exponentially suppressed relative to Λ_{soft} . The lightest Higgs H and the extra states are both heavier than the gauge boson mass, but suppressed relative to Λ_{soft} and $\Lambda_{(0)}$ by a factor of $\sqrt{\delta}$:

$$M_H \simeq \Lambda_{soft} \times \sqrt{\delta} \quad (3.25)$$

$$M_{extra} \simeq 4\pi v \times \sqrt{\delta} = \Lambda_{(0)} \times \sqrt{\delta}. \quad (3.26)$$

Insofar as we expect Λ_{soft} to be less than $\Lambda_{(0)}$, we see that the Higgs will be somewhat lighter than the extra states for comparable Yukawas. Note, however, that this separation

is independent of δ . We also see that the mass of the Higgs relative to the gauge bosons is:

$$\frac{M_H}{M_W} \simeq \frac{2}{g} \times \sqrt{\delta} \times (\sqrt{q_0})^{-1/\delta}. \quad (3.27)$$

In other words, we see that with $q_0 < 1$, as δ decreases the Higgs becomes heavier than the W -boson. However, since the ratio is quite sensitive to the value of δ , the mass of the Higgs can either be close to the LEP bound of 114 GeV, or far heavier.

It is also interesting to study the behavior of Λ_{soft} viewed as a function of the fixed mass scale M_W and the parameters g , q_0 and Δ :

$$\Lambda_{soft} \simeq \frac{2 M_W}{g} \times (\sqrt{q_0})^{-1/\delta}. \quad (3.28)$$

Note that since $\Lambda_{soft} \leq \Lambda_{(0)} \simeq 3$ TeV, naively it would seem that the Higgs mass can be increased by an arbitrary amount by increasing δ . However, the above formulae rely on a classical analysis of the Higgs potential where the SM gauge group is assumed to be weakly gauged. As a conservative estimate, for Higgs masses above around a TeV, weak gauge boson scattering ceases to be perturbative and partial-wave unitarity is violated [32]. Hence, when the Higgs mass becomes close to a TeV, the framework described in this work ceases to be valid. This breakdown in the analysis occurs when $\Lambda_{soft} \sim \Lambda_0 \sim 4\pi v$. Stated differently, the approximation scheme remains self-consistent provided:

$$4\pi > (\sqrt{q_0})^{-1/\delta}. \quad (3.29)$$

For $\delta = 0.01$, this implies $q_0 \gtrsim 0.95$, while for $\delta = 0.1$, this implies $q_0 \gtrsim 0.6$. Thus, q_0 is required to be close to one and less than one for consistency. We do not view this as a fine-tuning, since we are simply solving for q_0 as a function of δ . Indeed, when this condition is not satisfied, it simply means perturbation theory has broken down.

4 Precision Constraints

In the previous section we observed that the presence of a singular Kähler potential naturally increases the mass of the lightest Higgs boson relative to the W - and Z -boson masses. It is well known that in the absence of any additional physics, the precision electroweak fit favors a light ~ 100 GeV elementary Higgs.

In this section we study the consequences of such constraints in the DSSM. We mainly focus on the contributions to the oblique parameters S and T [30] as the U parameter is expected to be much smaller. Present electroweak fits yield an ellipse in the $S-T$ plane [33] which roughly lies along a 45° angle with major axis going from the lower left to the upper

right. Increasing the mass of the Higgs leads to a contribution to S and T which moves these values down and to the right of the ellipse. Hence, a positive contribution to T_{UV} and a negligible positive or negative contribution to S_{UV} is necessary in order to pass back within the 68% confidence level ellipse. To frame our discussion, recall that to lowest order S is defined as the coefficient of the operator $\frac{gg'}{16\pi} \Pi^\dagger W_{\mu\nu}^3 \Pi B^{\mu\nu}$, while T is the coefficient of $\frac{e^2}{8\pi c_W^2} v^2 \left| \text{Tr}_{SU(2)}(\tau^{(3)} \Pi D_\mu \Pi^\dagger) \right|^2$, where $\Pi = e^{i\frac{\vec{\pi}\cdot\vec{\tau}}{v}}$ and the $\tau^{(a)}$ are spin 1/2 generators of $SU(2)$. Our conventions are that we consider the contributions to these operators from all effects beyond the Standard Model. In our conventions, the Standard Model values are then $S_{SM} = 0$, $T_{SM} = 0$.

Let us preface our discussion with a general comment: Since we have only imperfect knowledge of the hidden conformal sector, and since it is strongly coupled, we shall only aim for order of magnitude estimates. It would be of interest to turn the discussion around, and use constraints from electroweak precision as a way to obtain insight about the properties of the hidden sector of the setup. The main conclusion we draw is that the contributions from the minimal inputs necessary to define the DSSM can accommodate constraints from precision electroweak. Also, we will first discuss the case where custodial $SU(2)$ is not preserved, and then discuss situations in which it could be approximately preserved.

We divide the contribution to S and T in two pieces - one is the “classical” UV contribution to the electroweak observables coming from expanding around a fixed Higgs vev, and the other is IR radiative contributions in the Higgs sector at energies of the order of Higgs masses and below:

$$S = S_{IR} + S_{UV} \tag{4.1}$$

$$T = T_{IR} + T_{UV} \tag{4.2}$$

For the radiative corrections from the Higgs sector, the Higgs fields are treated as a collection of ordinary weakly coupled fields. We expect the division into two pieces to at least roughly capture the physics. This is because the classical analysis of the scalar potential differs from the standard weakly coupled models due to a non-trivial Kähler potential, giving rise to a “classical UV” contribution. However, the fluctuations at low energies are close to that of weakly coupled fields (since Δ is close to 1) giving rise to a “radiative IR” contribution which is similar to that in weakly coupled models.

Consider first the IR contributions. These radiative contributions are of the standard type which have been extensively studied for two Higgs doublet models. We adopt the approximation scheme used in Appendix A of [14], and closely follow the discussion provided there. We split up the Higgs mass eigenstates h^0 , H^0 , $H^\pm$ and A^0 , into a Standard Model-

like scalar Higgs $\tilde{h}^0$ and an $SU(2)_L$ doublet:

$$H = \begin{bmatrix} H^+ \\ \frac{1}{\sqrt{2}} (\tilde{H}^0 + iA^0) \end{bmatrix} \quad (4.3)$$

where $\tilde{H}^0 = \cos(\beta - \alpha) h^0 - \sin(\beta - \alpha) H^0$ and $\tilde{h}^0$ is orthogonal to $\tilde{H}^0$. Our conventions for Higgs mixing angles are as in [34]. Since $\tilde{h}^0$ is not a mass eigenstate, it will have contributions from both h^0 and H^0 which can be treated in terms of a weighted sum. Similarly, $\tilde{H}^0$ is a linear combination of mass eigenstates. The full contribution to S_{IR} and T_{IR} can then be written, in this approximation, as a sum of the singlet and the doublet contributions:

$$S_{IR} \simeq S_{IR}^{\text{singlet}} + S_{IR}^{\text{doublet}}, \quad T_{IR} \simeq T_{IR}^{\text{singlet}} + T_{IR}^{\text{doublet}} \quad (4.4)$$

where the contribution from the singlet can be approximated as (see e.g. [30]):

$$S_{IR}^{\text{singlet}} \simeq \frac{1}{6\pi} \log \frac{\overline{M}_H}{M_Z}, \quad T_{IR}^{\text{singlet}} \simeq -\frac{3}{8\pi c_W^2} \log \frac{\overline{M}_H}{M_Z} \quad (4.5)$$

where $\overline{M}_H$ is the characteristic mass scale for the singlet Higgs, which behaves roughly like a SM higgs. For example, using a representative value $\overline{M}_H = 500$ GeV (see Appendix B for a rough sense of the mass scales involved), we find :

$$S_{IR}^{\text{singlet}} \approx +0.09; \quad T_{IR}^{\text{singlet}} \approx -0.26 \quad (4.6)$$

The contribution from the doublet is somewhat more involved. It is given by:

$$S_{IR}^{\text{doublet}} \simeq \sin^2(\beta - \alpha) F(M_{H^\pm}, M_{H^0}, M_{A^0}) + \cos^2(\beta - \alpha) F(M_{H^\pm}, M_{h^0}, M_{A^0}) \quad (4.7)$$

$$T_{IR}^{\text{doublet}} \simeq \frac{1}{16\pi M_W^2 s_W^2} [\sin^2(\beta - \alpha) G(M_{H^\pm}, M_{H^0}, M_{A^0}) + \cos^2(\beta - \alpha) G(M_{H^\pm}, M_{h^0}, M_{A^0})]$$

Here, F and G are complicated functions of their arguments (see Appendix A of [14]). However, qualitatively these contributions have the rough form:

$$F \approx c_F \times \log \frac{\overline{M}_H}{M_Z}, \quad G \approx c_G \times \overline{M}_H^2 \log \frac{\overline{M}_H}{M_Z} \quad (4.8)$$

where the c 's are order $0.1 - 1$ constants, and $\overline{M}_H$ is a characteristic mass scale in the arguments of F and G . Note that F is logarithmic in the Higgs masses, while G contains a quadratic piece. Depending on the Higgs mass spectrum, c_F and c_G can either be positive or negative. Using the explicit forms of F and G and various choices for the Higgs masses which could arise in the DSSM, we find that S_{IR}^{doublet} can vary between -0.1 and $+0.1$.

T_{IR}^{doublet} is far more sensitive to the Higgs masses, it can be either positive or negative with magnitude varying from around 0.1 to around 10. A “large” contribution $|T| \sim 10$ arises if custodial $SU(2)$ is violated in the Higgs spectrum. Let us note that having both S and T negative occurs only in a small range of parameter space, and in such cases, the magnitude of the parameters are bounded. Related scans of two Higgs doublet parameter space have been performed in [35] and very recently in [36]. In [36], it was also found that for some range of parameters a negative S and T could also be arranged. In our case, the difference with the perturbative two-Higgs doublet model arises due to additional “UV” contributions. For example, for the T parameter, the “classical UV” contribution coming from a non-trivial Kähler potential also violates custodial $SU(2)$ in general¹³; hence the full contribution can be within the allowed limits if they cancel each other. As will be seen below, the contribution to T_{UV} is positive, so a reasonable fit will require T_{IR} to be negative. This fixes some features of the Higgs masses but is still rather model-dependent, depending on the details of the Higgs spectrum.

Let us now turn to the various UV contributions. Consider first the contributions to the T_{UV} . In the approximation scheme we have adopted, the contribution from extra states of the conformal sector has already been included via the effective Kähler potential. This generates what we referred to in the previous section as the “classical” ρ_{cl} . This is because the effective Kähler potential for the Higgs fields encapsulates the effects of wave-function renormalization for the Goldstone modes via the interactions $H_u \mathcal{O}_u + H_d \mathcal{O}_d$. Hence, the UV contribution to T is estimated to be:

$$T_{UV} = x \times \frac{\delta}{\alpha} + \dots \quad (4.9)$$

where x is an order one positive number (typically smaller than one), and we have used the relation $\rho = 1 + \alpha T$ (see e.g. [30]). The “...” reflects possible additional contributions from supersymmetry breaking effects which, as in the MSSM, can be small. Thus, T_{UV} is around +10 for $\delta \simeq 0.1$ and around +1 for $\delta \simeq 0.01$. In order to remain in accord with precision electroweak, recall that the net contribution to T from the IR and UV needs to cancel to a number of order +0.1. Returning to equation (4.9), if we literally take $x = 1$, then for $\delta \simeq 0.01$, we have $T_{UV} \approx 1$. So one requires $T_{IR} \approx -1$, implying an order 10% tuning in the Higgs masses to fit within the 68% confidence ellipse¹⁴. On the other hand, for $\delta \simeq 0.1$, one requires an order 1% tuning. Note that the lower range of δ of order 0.01 also requires less tuning in the quark Yukawas, and leads to a better fit with precision gauge coupling unification. Perhaps this points to small δ being favored when there is no custodial $SU(2)$.

Consider next the contribution to S_{UV} . In explicit realizations of technicolor theories,

¹³Of course, it is possible to consider cases where custodial $SU(2)$ is approximately conserved, which is also discussed.

¹⁴This is, of course, the naive tuning. There is no objective measure of tuning.

the contribution to S_{UV} , based on extrapolation of QCD-like behavior, is a significant hurdle to overcome. However, this is not true for the theories under consideration. In addition to being supersymmetric and conformal above $\Lambda_{(0)}$, the strongly coupled theories which we consider are quite different from QCD (and SQCD). Thus, S does not scale like that in a traditional technicolor theory. Another important feature is that some of the states of the hidden sector will get masses which are roughly $SU(2)_L$ preserving. In the MSSM, the Higgs sector is vector-like with respect to $SU(2)_L \times U(1)_Y$ and the contributions from visible superpartners are negligible since supersymmetry breaking gives them $SU(2)_L$ preserving masses. Similar considerations apply in the quasi-hidden sectors considered in the present framework. Indeed, if supersymmetry breaking still gives the dominant contribution to the scalars of the hidden sector, they will have largely $SU(2)_L$ preserving masses.

The fermionic states, however, are assumed to primarily get their mass from the Higgs vev, so one might worry about the size of such contributions. It is hard to determine S_{UV} from first principles, but we will argue that it can naturally be small enough. If we just view the extra sector states as weakly coupled additional vector-like generations for simplicity, the contribution to the S parameter can be estimated to be $c_{extra} \times 1/6\pi$, where c_{extra} is a coefficient which depends on the representations under the electroweak gauge group as well as the details of Yukawa couplings (see for example [30, 37, 38]). For example, for the states appearing in (2.2), one gets:

$$c_{extra} = 8 - \log \left(\frac{\kappa_{QU} \tilde{\kappa}_{QD} \kappa_{LE} \tilde{\kappa}_{LS}}{\tilde{\kappa}_{QU} \kappa_{QD} \tilde{\kappa}_{LE} \kappa_{LS}} \right)^2 \quad (4.10)$$

Hence a slight hierarchy between the Yukawa couplings κ and $\tilde{\kappa}$ can give rise to $|c_{extra}| \lesssim 1$. In models with a single Higgs doublet¹⁵, the difference between the Yukawa couplings κ and $\tilde{\kappa}$ above leads to a large positive contribution to T which is a significant problem. However, since we have a two Higgs doublet model, this positive contribution can be cancelled by a negative contribution from T_{IR}^{doublet} as explained earlier.

Of course, one should not forget that viewing the extra states as weakly coupled vector-like generations description is not quite correct. In [39] it was found that the representation content of the extra states can affect the sign of S . Considering that whole towers of states with different electroweak representations contribute in the quasi-hidden CFT, this provides an indication that contributions from different representations can at least partially cancel each other, and either sign contributions to S_{UV} with $|c_{extra}| \lesssim 1$ may be possible¹⁶.

¹⁵such as usual technicolor models where the role of the Higgs doublet is played by a fermion condensate.

¹⁶As a related comment, though not strictly relevant for our present discussion, it is interesting to note that both the magnitude and sign of the analogue of S can be freely adjusted in supersymmetric $U(1) \times U(1)$ gauge theories. Indeed, viewing S as the size of the kinetic mixing between these two $U(1)$ factors, we observe that there is a 2×2 matrix of holomorphic gauge couplings τ_{ij} . In $\mathcal{N} = 2$ supersymmetric gauge theories, this matrix of couplings corresponds to the modular parameters of a genus two Riemann surface.

In addition, once conformal symmetry is broken in the hidden sector and electroweak symmetry is broken in the visible sector, both Dirac-type and Majorana-type (if allowed by gauge symmetry) mass terms for these states are generated. For example, given a vector like pair $L^{(4)} \oplus \tilde{L}^4$, the higher dimension operator $H_u H_d L^{(4)} \tilde{L}^{(4)} / M_{\text{CFT}}$ can generate a significant $SU(2)_L$ preserving mass for these states at strong coupling, which will lower their contribution to S_{UV} . The presence of Majorana mass terms for some of the extra states can give rise to negative contributions to S_{UV} [40], which can also partially cancel positive contributions from other states. Thus, combining all contributions $S \equiv S_{UV} + S_{IR}^{\text{singlet}} + S_{IR}^{\text{doublet}}$ can naturally lie between -0.1 and 0.1.

We now consider models in which the quasi-hidden sector enjoys an approximate $SU(2)_R$ flavor symmetry. This can occur in the present class of theories, with $SU(2)_R$ appearing as an emergent flavor symmetry in the infrared, and with the Higgs fields transforming in the $(2, 2)$ of $SU(2)_L \times SU(2)_R$.¹⁷ Note that in the deep IR, the Higgs fields would have the same dimension Δ . In this case, a diagonal $SU(2)_{\text{diag}} \subset SU(2)_L \times SU(2)_R$ functions as custodial $SU(2)$ when $\tan \beta = 1$, and deviations from this value correspond to an additional order parameter, $\varepsilon \simeq \tan \beta - 1$ (though even for $\tan \beta = 2$ there is some suppression). This leads to an extra suppression of the parameter x in equation (4.9) so that $T_{UV} \simeq \alpha^{-1} \times \varepsilon^2 \times \delta$ (see e.g. equation (3.17)). Hence, even with $\delta \simeq \varepsilon \simeq 0.1$, $T_{UV} \simeq 0.1$ can be obtained quite naturally leading to consistency with precision electroweak.

Such small values of $\tan \beta$ are a well-motivated possibility. In the DSSM, this can arise if $m_u^2 = m_d^2$. If $m_{u(0)}^2 = m_{u(0)}^2$ at the messenger scale, and provided the mediation scale is sufficiently low, there will not be sufficient RG time to distort this relation by a large amount.¹⁸

5 Collider Signatures

In this section we comment on the collider signatures of the framework. The collider phenomenology is quite rich, though also very dependent on details of the hidden sector. Consequently we restrict ourselves to making qualitative and general remarks which arise via the main features of the framework.

Recall that the main features of the DSSM are a modified Higgs sector, and an accompanying set of extra states, with respective masses:

$$M_H \simeq \sqrt{\delta} \times \Lambda_{\text{soft}}, \quad M_{\text{extra}} \simeq \sqrt{\delta} \times \Lambda_{(0)}. \quad (5.1)$$

In the special case of a genus two Riemann surface, the only requirement is that τ_{ij} is positive definite. In the perturbative regime, $\text{Im } \tau_{11}$ and $\text{Im } \tau_{22}$ are both large and positive. Hence, either sign of $\text{Im } \tau_{12}$ is in principle possible. It would be interesting to incorporate this observation into explicit models.

¹⁷An explicit example of this type is the “ S_3 monodromy” scenario of [5].

¹⁸For example, this could happen in gauge mediation with a low messenger scale.

These extra states transform in $SU(5)_{GUT}$ multiplets, and so have G_{SM} quantum numbers. Since $\Lambda_{(0)} \simeq 4\pi v \simeq 3$ TeV, we see that in the range $0.01 \leq \delta \leq 0.1$, this yields a mass scale roughly of order $300 \text{ GeV} \lesssim M_{extra} \lesssim 950 \text{ GeV}$. The precise mass, however, depends on order one Yukawa couplings to the hidden sector. This gives an order one uncertainty to the above estimates. Thus there is a rich hidden sector with “mesons” which are either charged or uncharged under G_{SM} . The main portal which connects the visible and hidden sector is the F-term deformation $H_u \mathcal{O}_u + H_d \mathcal{O}_d$.¹⁹

The fact that there is an approximate conformal sector consisting of states with non-trivial scaling dimensions coupled to the visible sector might at first suggest a scenario similar to unparticles [41]. However, in the DSSM the conformal symmetry is broken at the scale Λ_{soft} , which sets the scale for the soft masses around a TeV. Hence this framework should be viewed as a particular class of hidden valley models, namely SM charged unparticles with a mass gap [19, 20]. In addition, the Higgs sector can in principle mix with operators in the conformal sector. Such interactions can have important implications for Higgs physics, as discussed for example in [6, 15, 20]. See [21–24] for related work on the phenomenology of unparticle scenarios with a mass gap.

To look at the phenomenology in a bit more detail, we divide the discussion into two parts. By assumption, the states of the hidden sector fill out $SU(5)_{GUT}$ multiplets. Hence, we first discuss the phenomenology of the Higgs sector and the operators in the conformal sector charged under just $SU(2)_L \times U(1)_Y$, but neutral under $SU(3)_C$. Next, we comment on the additional states charged under $SU(3)_C$.

5.1 Electroweak Sector

Let us first make some general comments on the signatures of states charged under $SU(2)_L \times U(1)_Y$ but which are neutral under $SU(3)_C$. This includes the Higgs sector states, but also states of the hidden sector. The two sectors mix via couplings such as $H_u \mathcal{O}_u + H_d \mathcal{O}_d$, which can in principle have an important consequence for Higgs physics.

Up to now, we have implicitly assumed that the mixing between the Higgs and hidden sector states is small enough so that the Higgs fields retain their character. In a weakly coupled approximation (c.f. equation (2.2)), one can view $\mathcal{O}_u$ as containing $L^{(4)} S_u$, where $L^{(4)}$ has quantum numbers conjugate to H_u and S_u is a G_{SM} gauge singlet. If S_u then gets a vev, H_u and $L^{(4)}$ would also mix. It is natural to expect some of the singlets of the hidden sector to get a vev which gives the $U(1)_{hid}$ gauge boson a mass, as can occur in the D3-brane theories of [1, 5]. The possibility of large mixing with this hidden sector is quite interesting, but more difficult to analyze.

¹⁹In the D3-brane theories of [1, 5] there are additional mixing terms via the third generation, but to keep our discussion streamlined, we focus on just the minimal interaction term.

The case of small mixing is also well-motivated theoretically, and lends itself to an easier analysis. Small mixing can occur if a hidden sector singlet S_{hid} with excess dimension δ_{hid} experiences a squeezed Mexican hat potential so that the vev is $v_{hid} \simeq \Lambda_{soft} \times (q_{hid})^{1/2\delta_{hid}}$. Hence, even if the SM singlets of the hidden sector pick up vevs, this scale may be far below the Higgs vev, thus limiting the mixing between the Higgs and the extra $SU(2)_L \times U(1)_Y$ charged states.

Even in the case of weak mixing, the resulting phenomenology can be quite interesting as it can give rise to new production and decay modes of the Higgs. The main ideas can be conveyed by considering mesonic operators $\mathcal{O}_a \sim \phi_a^\dagger \phi_a$ of the hidden sector, where the ϕ_a can refer to states with or without $SU(2)_L \times U(1)_Y$ quantum numbers.²⁰ Production of an operator $\mathcal{O}_a \simeq \phi_a^\dagger \phi_a$ through gluon fusion could proceed followed by the decay $\phi^a \rightarrow \phi^b H$ if kinematically allowed, resulting in a channel such as $b\bar{b}\tau^+\tau^- + \text{missing energy}$ if ϕ^b decays to Standard Model neutral hidden sector states which are either stable or long-lived on collider time scales. On the other hand, for $m_H > 2m_{\phi_a}$, vector boson fusion or WH/ZH associated production followed by decays $H \rightarrow \phi_a \phi_a$, $\phi_a \rightarrow H^* \phi_b$ could result in forward jets and soft jets or leptons and missing energy.

Just as in other two Higgs doublet models, the lightest Higgs could have a different branching fraction to gauge bosons, as well as other Standard Model states. In fact, if it is sufficiently heavy, it may also decay to $t\bar{t}$. In addition to these more “standard” decay modes, there is the possibility that the Higgs can decay to hidden sector states or LSPs, reducing the branching ratio to visible sector states. Its branching ratio to two gluons and two photons will also be generically different than in the MSSM because of the presence of extra scalar and fermionic states which run inside the loop. Hence, the latest Higgs bounds from the LHC are generically weakened when interpreted within this framework. Of course, the precise form of the resulting signatures is model-dependent. At one extreme, if the extra states are heavier than the Higgs by a factor of $\Lambda_{(0)}/\Lambda_{soft}$, the main Higgs decays to the hidden sector involve higher dimension operators, which would be suppressed relative to decays to SM states. However, decays to LSPs, if the LSP is in the visible sector, may still occur with a non-trivial branching ratio. At the other extreme, if there is a significant mixing between the Higgs and the hidden sector, the resulting phenomenology will be quite rich and complicated. This could give rise to a scenario with multiple cascade decays of the Higgs (or the operators it mixes with) and high multiplicity in the final state. These kinds of signatures have been considered in [19, 20, 42] from a phenomenological perspective. We can therefore view the above framework as providing an explicit UV-motivated realization of such scenarios.

²⁰This strictly only makes sense if it is possible to view $\mathcal{O}_a$ as bound state of ϕ_a and $\phi_a^\dagger$.

5.2 Colored Sector

The DSSM also naturally contains states charged under $SU(3)_C$, which are necessary to retain gauge coupling unification. Given the significant improvement in search channels for light colored states coming from ATLAS and CMS, it is important to study the consequences of these searches for the present class of models.

The states of the hidden sector can decay when there are additional Yukawa couplings to the visible sector. This is what occurs, for example, in the string motivated scenarios of [1], where the third generation states couple to additional hidden sector operators. In many cases, these couplings are irrelevant, and so if we had flowed to the deep IR, would have vanished. However, since we have cutoff of the RG flow, they contribute an additional source of couplings which can allow colored (and uncolored) states of the hidden sector to decay. The decay of such states in related scenarios has been studied in [4]. For CFT breaking near the weak scale, the decay rate is on the order of $\Gamma \sim M_{weak}(M_{weak}/M_{GUT})^\nu$ for ν a small parameter related to the excess dimension of the third generation operators. This leads to decays which are prompt on the order of collider timescales.

Let us now discuss some additional features of these extra states. Since the states in the hidden conformal sector are supersymmetric, the scalar and fermionic operators have different R -parity assignments.²¹ The R -parity even states could be produced singly as a resonance. These states will eventually decay to visible jets (as required by color flow) and to hidden sector singlets, which could be much lighter. If these hidden sector singlet states are sufficiently heavy, they can also eventually decay back to the visible sector light quarks and leptons. This could happen for example through connector operators such as $\mathcal{O}_u, \mathcal{O}_d$ or hidden gauge bosons which mix with the Z . Thus, there could be multiple jets and/or leptons in the final state, many of which could be soft. Thus current bounds on such colored states from dijet searches such as [43] may not apply. If, on the other hand, these hidden sector singlet states are sufficiently light, then the decay processes involving a Standard Model charged extra state will involve a fewer number of jets with larger missing energy. Even in this case, however, the effects of strong coupling can in principle produce additional jets. This will affect the branching ratios of the various decay channels. More study is needed to determine the relevant bounds in this situation.

R -parity odd colored states, on the other hand, can only be pair-produced. Again, these could decay to visible jets and hidden non-colored states. The R -parity odd states in the hidden sector will eventually decay to multiple soft jets/leptons and the LSP. Recent

²¹We assume for concreteness that R -parity is conserved. In the particular context of F-theory GUT models, matter parity can be viewed as a discrete subgroup of a $U(1)$ Peccei-Quinn symmetry. This $U(1)_{PQ}$ originates from a flavor, e.g. $7'$ -brane which intersects the visible sector GUT 7 -brane. The visible sector states correspond to $7 - 7'$ strings, while the states of the D3-brane theory correspond to $3 - 7$ strings, and $3 - 7'$ strings. In other words, the states charged under $SU(5)_{GUT}$ coming from the D3-brane will have even matter parity, while the hidden sector states neutral under $SU(5)_{GUT}$ may have either matter parity.

ATLAS and CMS searches based on multiple jets + missing energy are sensitive to these processes, if there are enough hard jets to trigger on. In such cases, lower bounds on the masses of such states could be placed. However, it should be clear that the precise bounds depend on many model dependent details.

The presence of additional colored states from the hidden sector can also affect Higgs production. An important process of this type is gluon fusion, with a hidden sector colored state running in the corresponding loop. The size of this contribution is determined by the coefficient of the effective operator $(H/M_{extra})\text{Tr}_{SU(3)}F_{SU(3)}^2$. This is in turn controlled by the one loop beta function contribution from new states, as explained for example in [44,45]. At high scales where supersymmetry is restored, the size of this threshold correction for representative DSSM scenarios has been computed in [2], which we can interpret as the coefficient of the Hgg vertex generated by such corrections. In this limit, the contribution can lead to a sizable increase in the Higgs production cross section (a factor of roughly $O(1) - O(10)$). In the presence of supersymmetry breaking effects, however, the form of such threshold corrections is more subtle. For example, when the soft masses and mixing terms for the stop sector of the MSSM are comparable in size, the contribution to the gluon fusion effective vertex from the top and stop sector can cancel [46,47]. Similar considerations apply for colored hidden sector states. Indeed, the generic expectation is that the soft masses and A-terms of the hidden sector will naturally be of similar scale. In addition, there can be additional suppression/enhancement of gluon fusion due to the dependence on the mixing angles in a general two Higgs doublet sector (see for example [48] for a review). Thus, we can expect that there exist regions of parameter space in the hidden sector where the Higgs production can be similar to that in the MSSM, or perhaps even reduced. As a final, less motivated possibility, one might also consider scenarios where the colored extra states receive an additional large (compared to the electroweak scale) contribution to their masses, leaving only uncolored objects in the low energy spectrum. In such cases, the contribution from the hidden sector to processes such as gluon fusion would almost be the same as in the MSSM. Turning the discussion around, collider constraints on the product of the Higgs production cross section and branching fraction can then impose constraints on the properties of the hidden sector. The basic feature, however, is that based on the qualitative considerations just discussed, we can expect large regions of parameter space in the hidden sector to be in accord with present constraints on the Higgs sector.

6 Conclusions

A natural feature of many supersymmetric theories is a non-trivial Kähler potential. In this paper we have investigated the consequences of a class of singular Kähler potentials which would naturally arise if the Higgs interacts with a quasi-hidden sector. We have

seen that even in the limit where the Higgs fields have dimension close to one, gauge boson masses are naturally lower than the Higgs mass. This situation is quite different from the MSSM. Moreover, whereas many models with a strongly coupled Higgs also face significant obstacles with low Landau poles, we have seen that the present class of models can naturally accommodate precision gauge coupling unification as well as large quark Yukawas, while still being consistent with electroweak precision constraints. The singular nature of the Kähler potential also indicates the presence of additional colored and uncolored states close to the Higgs mass.

Some potential avenues of future investigation are as follows. Our analysis in this paper has focussed on the low energy consequences of making the Higgs have non-trivial scaling dimension. It would be quite interesting to realize a more UV-complete version of these dynamics which includes both a supersymmetry breaking sector, and means of transmission to the visible sector. The more general lesson we have arrived at is that a non-trivial Kähler potential can lead to novel and phenomenologically viable models of electroweak symmetry breaking. It would be quite interesting to widen the scope of our investigation to study the broadest possible Kähler potential consistent with present phenomenological constraints.

The DSSM predicts extra states, leading to a potentially rich phenomenology which is also quite model-dependent. Given the data being accumulated at the LHC, a comprehensive study of even some representative examples would be extremely interesting.

A Review of D3-Brane CFTs

In this Appendix we provide a brief review of some of the properties of the D3-brane CFTs introduced in [1] and studied further in [2–5]. Though the natural setting for these

CFTs is from a string construction, many of their properties can be stated in purely field theory terms. The starting point is a four-dimensional conformal field theory with $\mathcal{N} = 2$ supersymmetry. From these “master theories” other conformal field theories can be obtained by performing relevant deformations to new theories with $\mathcal{N} = 1$ supersymmetry.

The starting “master theories” are known as Minahan-Nemeschansky E-type theories [49, 50]. These are four-dimensional theories with $\mathcal{N} = 2$ supersymmetry and a flavor symmetry which is E_6 , E_7 or E_8 . For concreteness, we focus on the E_8 theory, since the others can be obtained from deformations of this one. These theories are intrinsically strongly coupled, and there is no known weakly coupled Lagrangian description available. The lack of such a description does not mean such theories are inaccessible to study. Indeed, the absence of a Lagrangian is compensated by the presence of $\mathcal{N} = 2$ supersymmetry and the associated Seiberg-Witten curve. The operators of this theory transform in representations of E_8 . There is a particular class of operators $\mathcal{O}_{248}$ transforming in the 248 (adjoint) of E_8 . These operators have dimension two and can loosely be thought of as the analogue of the mesons in SQCD.

From this $\mathcal{N} = 2$ master theory we obtain the $\mathcal{N} = 1$ CFTs describing the D3-brane probe CFTs of [1]. We view the SM gauge group as embedded in E_8 via:

$$G_{SM} \subset SU(5)_{GUT} \subset SU(5)_{GUT} \times SU(5)_{\perp} \subset E_8. \quad (\text{A.1})$$

This is obtained by switching on operator deformations of the $\mathcal{N} = 2$ theory involving the dimension two “mesonic” operators. Such deformations break the flavor symmetry E_8 to $SU(5)_{GUT}$. These deformations generically also break $\mathcal{N} = 2$ to $\mathcal{N} = 1$. The original operators $\mathcal{O}_{248}$ then decompose into irreducible representations of G_{SM} . In particular, some of these operators will have quantum numbers conjugate to the Standard Model fields. One therefore expects the operator deformations:

$$\int d^2\theta \, \Psi_R \mathcal{O}_{\overline{R}} \quad (\text{A.2})$$

for Ψ_R a chiral superfield of the MSSM in representation R of G_{SM} , and $\mathcal{O}_{\overline{R}}$ an operator in the conjugate representation. This leads to operator couplings such as:

$$\int d^2\theta \, (H_u \mathcal{O}_u + H_d \mathcal{O}_d). \quad (\text{A.3})$$

Let us note that in the stringy realization of these theories, there are typically additional couplings to the third generation:

$$\int d^2\theta \, \Psi_R^{(3)} \mathcal{O}_{\overline{R}} \quad (\text{A.4})$$

which can also alter the dimension of the third generation fields. We emphasize that such couplings are simply a part of the UV definition of the theory, and must be included in a consistent UV treatment. Of course, from the perspective of the low energy field theory, one can switch off such couplings. In this paper we have mainly focussed on the simplest realization of a DSSM where only mixing with the Higgs fields is included.

Including all of these operator deformations, one can use the powerful technique of α -maximization [51] to determine the resulting dimensions of the Higgs and other SM fields. A remarkable feature of many of these infrared fixed points is that the chiral superfields of the visible sector have scaling dimensions which are close to one. That is, the visible sector retains its identity, even in the deep infrared.

B Explicit Example

In this Appendix we study the mass spectrum in a situation where the doublets $H_u = (H_u^+, H_u^0)$ and $H_d = (H_d^0, H_d^-)$ both have dimension Δ , and the Kähler potential is taken to be:

$$K_\Delta = (H_u^\dagger H_u + H_d^\dagger H_d)^{1/\Delta}. \quad (\text{B.1})$$

This choice of Kähler potential has the additional benefit of preserving $SU(2)_L \times SU(2)_R$, where the Higgs doublets transform in the $(2, 2)$. This extra $SU(2)_R$ means that custodial $SU(2)$ can also be preserved near the $\tan \beta \rightarrow 1$ limit (see equation (3.17)).

A general discussion of supersymmetric Lagrangians with a non-trivial Kähler potential is given in [52,53], and a review can be found in chapter XXIV of [54]. Focussing on the Higgs sector, the system of interest consists of a four-component vector $\Phi^i = (H_u^+, H_u^0, H_d^0, H_d^-)$ given by the usual two Higgs doublets. The Lagrangian of the scalar fields is:

$$L_{\text{scalar}} = -g_{i\bar{j}} D_\mu \Phi^i D^\mu \Phi^{\dagger\bar{j}} - \frac{1}{2} g^2 D^{(a)} D^{(a)} - \frac{1}{2} g'^2 D^2 - g^{i\bar{j}} \partial_i W \partial_{\bar{j}} W^\dagger \quad (\text{B.2})$$

where W is the superpotential, and the auxiliary fields $D^{(a)}$ and D of the vector multiplet associated with $SU(2)_L \times U(1)_Y$ are:

$$D^{(a)} = -\frac{1}{\Delta} \left(H_u^\dagger \cdot \tau^{(a)} \cdot H_u + H_d^\dagger \cdot \tau^{(a)} \cdot H_d \right) \times \left(H_u^\dagger H_u + H_d^\dagger H_d \right)^{(1-\Delta)/\Delta} \quad (\text{B.3})$$

$$D = -\frac{1}{2\Delta} \left(H_u^\dagger H_u - H_d^\dagger H_d \right) \times \left(H_u^\dagger H_u + H_d^\dagger H_d \right)^{(1-\Delta)/\Delta} \quad (\text{B.4})$$

where the $\tau^{(a)}$'s are spin 1/2 generators of $SU(2)$.

In the remainder of this section we study two particular scenarios, one with $\tan \beta = 1$ and one with $\tan \beta = \infty$. Our notation for the physical Higgs spectrum is as in [34], e.g.

Figure 2: Plot of Higgs boson masses for a representative scenario with $\tan \beta = 1$. The numerical values used in the plot are $B_0 = 1$, $m_0^2 = 0$ and $q_0 = 0.9$. In these plots, the mass of the Z -boson has been held fixed at its observed value. By inspection, we see that as $\Delta \rightarrow 1$, the resulting masses diverge. Observe that at Δ near one, $H^{(0)}$ is the lightest neutral Higgs, while near two, $h^{(0)}$ is the lightest neutral Higgs.

$(h^0, H^0, A^0, H^+, H^-)$, with corresponding mixing angles $\alpha, \beta_{\pm}, \beta_0$. See figures 2 and 3 for plots of the mass spectra in these cases. The rest of the supersymmetric Higgs sector, in particular the mixing with gauginos in the chargino and neutralino system, can be determined using the general expressions given in [54]. The end result is not particularly illuminating, so we suppress it in what follows.

B.1 $\tan \beta = 1$

In this section we study a choice of parameters which leads to electroweak symmetry breaking with $\tan \beta = 1$. To realize this case, we take $m_u^2 = m_d^2$. In the weakly coupled MSSM, the limit $\tan \beta \rightarrow 1$ does not admit a metastable vacuum which both breaks electroweak symmetry and is bounded from below. Here we show that such critical points do exist in the DSSM, and we study the resulting mass spectra. To further simplify our analysis, we also take the soft masses to vanish. None of our qualitative conclusions depend on this requirement.

In this case, the Higgs vev in this symmetry breaking minimum are:

$$v_u^2 = v_d^2 = \frac{1}{2} \Lambda_{soft}^{2\Delta} \times (q_0)^{\Delta/(\Delta-1)}. \quad (\text{B.5})$$

Here, the parameter q_0 is a dimensionless ratio of the parameters of the theory:

$$q_0 = \frac{B_0/\mu_0^2}{2\Delta^2 - \Delta}. \quad (\text{B.6})$$

Consistency of the approximation we are considering requires the dimensionless ratio $q_0 < 1$. Let us note that if we view the soft breaking parameters as radiatively generated, and in particular, smaller than the supersymmetry preserving term μ_0 , this type of situation can be arranged.²²

Let us now summarize the mass spectrum of the various states which are in direct contact with our Higgs operators. The gauge boson masses squared are:

$$\frac{M_{W,cl}^2}{\Lambda_{soft}^2} = \frac{g^2}{2\Delta} \times (q_0)^{1/(\Delta-1)}, \quad \frac{M_{Z,cl}^2}{\Lambda_{soft}^2} = \frac{g^2 + g'^2}{2\Delta} \times (q_0)^{1/(\Delta-1)}. \quad (\text{B.7})$$

The parameter Λ_{soft} which defines the scale of soft supersymmetry breaking parameters in the Higgs potential is related to the Z-boson mass squared:

$$\frac{\Lambda_{soft}^2}{M_{Z,cl}^2} = \frac{2\Delta}{g^2 + g'^2} (q_0)^{-1/(\Delta-1)}. \quad (\text{B.8})$$

The Higgs mixing angles are:

$$\cos \beta_0 = \sin \beta_0 = \cos \beta_{\pm} = \sin \beta_{\pm} = \cos \alpha = \sin \alpha = 1/\sqrt{2}. \quad (\text{B.9})$$

²²As a simple example in the context of the MSSM, we note that if the μ -term is generated at some messenger scale but the $B\mu$ -term vanishes at this boundary condition, $B\mu$ will be radiatively generated, and naturally suppressed relative to μ^2 . However, it can still be larger in magnitude than the soft masses squared. Finally, we note that in gauge mediation scenarios, the requirement $m_u^2 = m_d^2$ at the messenger scale is also easily arranged. Provided the messenger scale is not too high, this leads to similar Higgs potentials to those we study here.

The Higgs masses squared are:

$$\frac{M_{h^{(0)}}^2}{M_Z^2} = \frac{4\Delta^3 \times (q_0)^{(\Delta-2)/(\Delta-1)}}{g^2 + g'^2} \times \frac{1}{\Delta} \times \left(\left(\frac{1}{2\Delta-1} \right) B_0 + \frac{g^2 + g'^2}{4\Delta^2} \times (q_0)^{(2-\Delta)/(\Delta-1)} \right) \quad (\text{B.10})$$

$$\frac{M_{H^{(0)}}^2}{M_Z^2} = \frac{4\Delta^3 \times (q_0)^{(\Delta-2)/(\Delta-1)}}{g^2 + g'^2} \times \left(\frac{\Delta-1}{\Delta} \right) \times B_0 \quad (\text{B.11})$$

$$\frac{M_{A^{(0)}}^2}{M_Z^2} = \frac{4\Delta^3 \times (q_0)^{(\Delta-2)/(\Delta-1)}}{g^2 + g'^2} \times B_0 \quad (\text{B.12})$$

$$\frac{M_{H^{(\pm)}}^2}{M_Z^2} = \frac{4\Delta^3 \times (q_0)^{(\Delta-2)/(\Delta-1)}}{g^2 + g'^2} \times \frac{1}{\Delta} \times \left(\left(\frac{1}{2\Delta-1} \right) B_0 + \frac{g^2}{4\Delta^2} \times (q_0)^{(2-\Delta)/(\Delta-1)} \right). \quad (\text{B.13})$$

From this behavior, we see that $(H^{(+)}, h^{(0)}, H^{(-)})$ form an approximate triplet of custodial $SU(2)$, with masses of the same size as Λ_{soft} . Moreover, near $\Delta \rightarrow 1$, $H^{(0)}$ is the lightest Higgs, while in the other limit where $\Delta \rightarrow 2$, $h^{(0)}$ is the lightest Higgs. Observe also that the relative mass of the Higgs bosons to the gauge boson masses is quite sensitive to the value of the parameter q_0 , and in particular, the overall factor of $(q_0)^{(\Delta-2)/(\Delta-1)}$. Since $1 < \Delta < 2$, observe that for $q_0 < 1$, the Higgs is parametrically heavier. One should exercise some caution because this is really a tree level analysis; as we push the Higgs mass above 800 GeV, gauge boson scattering ceases to be perturbative.

B.2 $\tan\beta = \infty$

We now study the Higgs masses in the opposite limit where $B = 0$ and we take a particular limit where the up-type soft masses are tachyonic, while the down-type soft masses are regular. This leads to $\tan\beta = \infty$, namely H_u alone gets a vev. Similar symmetry breaking patterns can be arranged in the MSSM. To simplify the analysis further, we drop the contribution from the D-terms, as it is a very small change in the form of the potential.

With this approximation scheme, the Higgs vevs satisfy:

$$v_u^2 = \Lambda_{soft}^{2\Delta} \times (q_0)^{\Delta/(\Delta-1)}, \quad v_d^2 = 0 \quad (\text{B.14})$$

where the dimensionless constant q_0 is:

$$q_0 = \left(\frac{-m_{u(0)}^2/\mu_{(0)}^2}{2\Delta^4 - \Delta^3} \right)^{1/2}. \quad (\text{B.15})$$

Note that in order to achieve a symmetry breaking vev, $m_{u(0)}^2 < 0$. The gauge boson masses

Figure 3: Plot of Higgs boson masses for a representative scenario with $\tan \beta = \infty$. The numerical values used in the plot are $B_0 = 0$, $m_{u(0)}^2 = -1$, $m_{d(0)}^2 = +1$ and $q_0 = 0.9$. In these plots, the mass of the Z -boson has been held fixed at its observed value. By inspection, we see that as $\Delta \rightarrow 1$, the resulting masses diverge. Observe that in this case $h^{(0)}$ is always the lightest Higgs.

squared are:

$$\frac{M_{W,cl}^2}{\Lambda_{soft}^2} = \frac{g^2}{2\Delta} \times (q_0)^{1/(\Delta-1)}, \quad \frac{M_{Z,cl}^2}{\Lambda_{soft}^2} = \frac{g^2 + g'^2}{2\Delta^2} \times (q_0)^{1/(\Delta-1)}. \quad (\text{B.16})$$

Observe that in this case, ρ_{cl} is proportional to Δ .

The analysis of Goldstone modes in this situation is actually much simpler. In this limit we have $\cos \beta_0 = \cos \beta_+ = 0$, and the two physically equivalent branches $\sin \alpha = 0$ and $\cos \alpha = 0$. We specify the form of the spectrum for the choice of mixing angles:

$$\cos \beta_0 = \cos \beta_+ = \sin \alpha = 0. \quad (\text{B.17})$$

The resulting Higgs masses squared, are, in units of the Z -boson mass:

$$\frac{M_{h^{(0)}}^2}{M_Z^2} = \frac{(q_0)^{-1/(\Delta-1)}}{g^2 + g'^2} \times (\Delta - 1) \times (-8m_{u^{(0)}}^2) \quad (\text{B.18})$$

$$\frac{M_{H^{(0)}}^2}{M_Z^2} = \frac{(q_0)^{-1/(\Delta-1)}}{g^2 + g'^2} \times \frac{2\Delta}{2\Delta - 1} \times (-m_{u^{(0)}}^2(6\Delta - 5) + m_{d^{(0)}}^2(2\Delta - 1)) \quad (\text{B.19})$$

$$\frac{M_{A^{(0)}}^2}{M_Z^2} = \frac{(q_0)^{-1/(\Delta-1)}}{g^2 + g'^2} \times \frac{2\Delta}{2\Delta - 1} \times (-m_{u^{(0)}}^2(6\Delta - 5) + m_{d^{(0)}}^2(2\Delta - 1)) \quad (\text{B.20})$$

$$\frac{M_{H^{(\pm)}}^2}{M_Z^2} = \frac{(q_0)^{-1/(\Delta-1)}}{g^2 + g'^2} \times 2\Delta \times (-m_{u^{(0)}}^2 + m_{d^{(0)}}^2) \quad (\text{B.21})$$

We observe that $h^{(0)}$ is the lightest Higgs. Next lightest are the charged Higgs fields $H^{(+)}$ and $H^{(-)}$. Finally, the heaviest Higgs bosons are $A^{(0)}$ and $H^{(0)}$, which are degenerate at this level of approximation. See figure 3 for a plot of these masses as a function of Δ .
